Symptom response to antibiotic prescribing strategies in acute sore throat in adults: the DESCARTE prospective cohort study in UK general practice

Abstract

Background
A delayed or ‘just in case’ prescription has been identified as having potential to reduce antibiotic use in sore throat.

Aim
To determine the symptomatic outcome of acute sore throat in adults according to antibiotic prescription strategy in routine care.

Design and setting
A secondary analysis of the DESCARTE (Decision rule for the Symptoms and Complications of Acute Red Throat in Everyday practice) prospective cohort study comprising adults aged ≥16 years presenting with acute sore throat (≤2 weeks’ duration) managed with treatment as usual in primary care in the UK.

Method
A random sample of 2876 people from the full cohort were requested to complete a symptom diary. A brief clinical proforma was used to collect symptom severity and examination findings at presentation. Outcome details were collected by notes review and a detailed symptom diary. The primary outcome was poorer ‘global’ symptom control (defined as longer than the median duration or higher than median symptom severity). Analyses controlled for confounding by indication (prescription to prescribe antibiotics).

Results
A total of 1629/2876 (57%) of those requested returned a symptom diary, of whom 1512 had information on prescribing strategy. The proportion with poorer global symptom control was greater in those not prescribed antibiotics 441/728 (61%) or delayed 398/587 (68%) compared with those prescribed antibiotics.1,4 An alternative strategy — using a delayed antibiotic prescription — has been shown to reduce antibiotic uptake without any effect on recovery or patient satisfaction,3 and to confer a similar protective effect against complications as an immediate prescription.6 However, the rationale of a delayed prescription has been called into question because it results in higher antibiotic uptake than a no prescription strategy, with a suggestion that a delayed strategy is inferior to immediate antibiotics for some sore throat symptoms.7 Observational studies provide useful evidence to complement experimental studies, given the concerns that randomised trial participants and their behaviour during trials (such as relating to adherences) may be atypical, and hence that estimates of effectiveness may not be applicable to patients consulting routinely.

In order to describe current practice and outcome related to prescribing strategy in adults, a large observational cohort that had been recruited to examine potential prediction of septic complications of acute sore throat was investigated. In a subset of participants completing a symptom diary, the symptomatic outcomes and illness duration in relation to prescribing strategy were analysed.

METHOD

Study design
This was a secondary analysis of the DESCARTE (Decision rule for the Symptoms and Complications of Acute Red Throat in Everyday practice) study, which as reported elsewhere was a large prospective cohort of patients presenting with acute sore throat in routine primary care in the UK.8,9 A simple one-page paper and/or web-based case

INTRODUCTION

Acute sore throat is common in everyday practice in primary care and antibiotics are still frequently prescribed.1 The Cochrane Review of acute sore throat management1 included 27 trials and more than 12,000 cases of acute sore throat, and found that antibiotics reduced the duration of pain symptoms by an average of 1 day. Current UK guidelines recommend a delayed or no prescription strategy for acute sore throat.2 Despite the guidelines and systematic review evidence described, most patients presenting with acute sore throat are prescribed immediate antibiotics.1,4 An alternative strategy — using a delayed antibiotic prescription — has been shown to reduce antibiotic uptake without any effect on recovery or patient satisfaction,3 and to confer a similar protective effect against complications as an immediate prescription.6 However, the rationale of a delayed prescription has been called into question because it results in higher antibiotic uptake than a no prescription strategy, with a suggestion that a delayed strategy is inferior to immediate antibiotics for some sore throat symptoms.7 Observational studies provide useful evidence to complement experimental studies, given the concerns that randomised trial participants and their behaviour during trials (such as relating to adherences) may be atypical, and hence that estimates of effectiveness may not be applicable to patients consulting routinely.

In order to describe current practice and outcome related to prescribing strategy in adults, a large observational cohort that had been recruited to examine potential prediction of septic complications of acute sore throat was investigated. In a subset of participants completing a symptom diary, the symptomatic outcomes and illness duration in relation to prescribing strategy were analysed.

METHOD

Study design
This was a secondary analysis of the DESCARTE (Decision rule for the Symptoms and Complications of Acute Red Throat in Everyday practice) study, which as reported elsewhere was a large prospective cohort of patients presenting with acute sore throat in routine primary care in the UK.8,9 A simple one-page paper and/or web-based case
report form (CRF) was used to document clinical features at presentation. Smaller studies were nested in the cohort to develop and trial a clinical scoring method for bacterial infection. The nested studies were two consecutive diagnostic cohorts (n = 1107) where a clinical score to predict bacterial infection was developed, and a randomised trial (n = 1781) that compared the use of the clinical score and the targeted use of a rapid antigen detection test with delayed antibiotic prescribing.9 Participants in the trial were not included in this analysis because antibiotics were targeted according to trial criteria. Recruitment took place between 10 November 2006 and 1 June 2009, from 616 recruiting practices. Initial recruitment was among six local networks (based in Southampton, Bristol, Birmingham, Oxford, Cardiff, and Exeter) but was extended nationally during the last 18 months of recruitment.

Patient inclusion criteria
Inclusion criteria were previously well patients aged ≥16 years with acute illness (≤14 days), presenting in primary care with sore throat as the main symptom, and with an abnormal examination of the pharynx (identical criteria to the authors’ previous studies).5 Exclusion criteria were severe mental health problems (such as cognitive impairment associated with being unable to consent or assess history) and known immune suppression. GPs recorded a detailed history and examination findings, and then treated the patient as usual. Antibiotic treatment was therefore determined by individual practitioners in accordance with their usual practice.

Baseline clinical proforma
A simple clinical sheet was used to document age, sex, current smoking status, prior duration of illness, and the presence and severity of baseline symptoms (sore throat, difficulty swallowing, fever during the illness, runny nose, cough, feeling unwell, diarrhoea, vomiting, abdominal pain, headache, muscle ache, sleep disturbance, and earache). Symptoms were recorded using a 4-point Likert scale (none, a slight problem, a moderately bad problem, or a severe problem), and the presence of signs (pus, cervical nodes, temperature, fetor, palatal oedema, and difficulty speaking because of sore throat). No laboratory tests were specified.

Documentation of primary outcome
A request to complete a symptom diary was randomly allocated to a proportion of those recruited to the study to achieve a pre-specified target of 1800 diaries. Initial allocation was randomly allocated to one in 10 participants by including the diary in recruitment packs. The allocation ratio was altered part way through the study to one in two packs in most centres, on account of observed low return rates. Allocation was one in four recruitment packs in Southampton because of the inclusion of an alternative questionnaire. The diary was similar to that used in other studies.5,10 Patients completed the diary each night until symptoms resolved or for up to 14 nights. Each symptom was scored (from 0 = no problem to 6 = as bad as it could be): sore throat, difficulty swallowing, feeling unwell, fever, and sleep disturbance. Adverse symptomatic outcome was defined as being either above the median for symptom severity at day 2–4 or above the median duration of moderately bad symptoms, that is, either or both qualified for adverse symptomatic outcome.

Other outcomes
In order to allow comparison with other studies, symptom severity on day 2–4 and the duration of moderately bad symptoms (in days) were also assessed.5,10

Sample size
Sample size calculations calculated using nQuery for the main study were based on the prediction of complications — a rare outcome. For the proposed analysis of diary data, a sample of 1800 patients allowing for 20% loss to follow-up of diaries (900 of whom would not be expected to have antibiotics), would have power to detect variables with prevalence between 20% to 80%, with an odds ratio of 2 for adverse symptomatic outcome among the no antibiotic group.
Analysis
Duration of symptoms was analysed using Cox regression, linear regression was used for symptom severity, and a generalised linear model with a log link and binomial distribution was used for worsening of illness and adverse symptomatic outcome. Missing data on outcome were not imputed. Both the univariate statistics and the relationships after controlling for the severity of all baseline symptoms and clustering of patients by practice are reported.

The Centor score, used widely to target treatment at those at higher risk of streptococcal infection, was derived in an emergency room setting where a score of ≥3 predicted a 32% risk of positive culture. The FeverPAIN score, which comprises fever in the past 24 hours, purulence, rapid (within 3 days) attendance, inflamed tonsils, and no cough or cold symptoms, may also be used to predict the probability of streptococcal infection in community samples and has been shown to be highly predictive of time to symptom resolution and symptom severity. An interaction between Centor/FeverPAIN and antibiotic prescribing strategy was tested for, which was to determine if those more likely to have streptococcal infection had evidence of a differential response to antibiotics. The scores were used to dichotomise the sample into those more or less likely to have a streptococcal infection: for Centor a cut-off point of ≥3 was used and for FeverPAIN a cut-off point of 0–2 versus ≥3 was used. For FeverPAIN at the cut-off point of 0–2 the probability of a streptococcus swab positive result is 26%, while for those with a score of ≥3 it is 60%. For Centor the probability of a streptococcus swab positive result is 15% for those with a score of 2 and 32% for those with a score of 3 or above. Analyses were carried out in Stata (version 12.1). To control for potential confounding by indication, a propensity score based on predictors of antibiotic prescribing (none versus immediate and none versus delayed) was calculated using a chained equations multiple imputation model. Results are presented both for complete cases and for models with significant predictors of the propensity score imputed. Outcome measures were not imputed because it

was not possible to distinguish between individuals who were missing data because they did not complete a diary when asked and those who were not asked to complete one.

**RESULTS**

**Descriptive data**

In the full cohort study, 14,610 adult patients were recruited between 10 November 2006 and 1 June 2009 from 616 general medical practices. A total of 1629/2876 (57%) returned a symptom diary, of whom 1512 had information on prescribing strategy. The baseline characteristics of patients recruited and of those who maintained a symptom diary are shown in Appendix 1. Those given immediate antibiotics had more severe symptoms at baseline and were more likely to have a history of fever and severe inflammation or pus on tonsils. In those returning the diary, no antibiotics were prescribed for 587/1512 (39%), immediate antibiotics were prescribed for 728/1512 (48%), and delayed antibiotics were prescribed for 197/1512 (13%). These are similar to the proportions prescribed to the full cohort: 4805/12,677 (38%), immediate antibiotics 6088/12,677 (48%), and delayed antibiotics 1784/12,677 (14%), respectively. In those completing a diary, 115/197 (58%) of those given a delayed prescription reported using the prescription. Delayed prescribing was only reported by those recruited from approximately one half of participating practices 320/616 (52%).

### Impact of prescribing strategies on symptom control

When controlling for propensity to prescribe antibiotics compared with no antibiotics, those prescribed immediate or delayed antibiotics experienced a reduction in poorer symptomatic outcomes: no antibiotics 398/587 (68%), immediate antibiotics 441/728 (61%), and delayed antibiotics 116/197 (59%); adjusted risk ratio (RR) [95% confidence intervals (CIs)] immediate RR 0.87 (95% CI = 0.70 to 0.96), P = 0.006; delayed 0.88 (5% CI = 0.78 to 1.00), P = 0.042 (Table 1). This finding was consistent when controlling for baseline severity.

Secondary outcomes showed a reduction in symptom severity on days 2–4 (Table 2). On average, 1 day less of moderately bad symptoms was experienced by those prescribed an immediate antibiotic (no antibiotic: median 4 days, interquartile range [IQR] 2–7 days; immediate: median 3 days, IQR 2–5 days; delayed: median 3 days, IQR 2–6 days) (Table 3). Hazard ratio (HR) controlling for propensity score for immediate prescribing was 1.21 (95% CI = 1.18 to 1.30), P < 0.001 for delayed prescribing was 1.10 (95% CI = 0.98 to 1.30), P = 0.084 (Table 3). The duration of moderately bad symptoms is illustrated in Figure 1.

### Evidence for a differential effect of antibiotic prescribing among those more likely to have bacterial infection

Although throat swabs were not collected, diary scores were used to predict the probability of streptococcal infection, and a subgroup of patients was created in whom bacterial infection was more likely as defined by a higher Centor Score (≥3) and FeverPAIN score (≥3). In this subgroup, the estimates of benefit were slightly greater than in the whole cohort for those given an immediate antibiotic prescription or delayed prescription (Tables 4 and 5). However, the difference between the subgroup and the main cohort was modest.

and statistically significant interactions were not powered for and were not found with the feverPAIN and Centor subgroups. The fact that those in these high-risk subgroups were overwhelmingly treated with immediate antibiotics further reduced the power of these analyses, particularly for the smaller numbers who were given delayed prescription. Individual secondary outcomes and point estimates for those at low/high risk of streptococcal infection are available from the authors on request.

DISCUSSION
Summary
This large cohort of patients presenting to general practice with acute sore throat enabled the authors to study the effect of prescribing antibiotics in routine practice on symptom severity and speed of illness resolution. Compared with a no antibiotic strategy, a delayed antibiotic strategy confers similar benefits to immediate antibiotics with regards to effects on global symptom outcome. Those prescribed immediate antibiotics experienced both a reduction in symptom severity on day 2–4 and a reduction in the duration of moderately bad symptoms of 1 day. Similar benefits were observed in those receiving a delayed prescription, although this study has limited power for some outcomes in this group.

Strengths and limitations
The study was designed using a simple clinical proforma to minimise selection bias and thus to produce a large generalisable prospective cohort. Patients were recruited at the busiest seasons for respiratory illness, and, as with other studies of acute infection, documentation of the details of those not approached was poor as a result of time pressures (because time pressure to recruit also meant time pressure to document non-recruitment).

The large sample gathered in routine practice, along with the inclusion of diary data, enabled the study of different antibiotic strategies and duration of prescription on symptomatic outcomes and re-consultation, which is likely to reflect the real-life experience of patients. The prescription of antibiotics, however, is not at random and there is clear evidence of a greater propensity to prescribe for those with more severe symptoms at baseline (Appendix 1). Despite adjusting for propensity to prescribe and presenting outcomes controlled for baseline severity of symptoms, it is not possible to rule out residual confounding.

It is possible that patients who were given a prescription for antibiotics subsequently altered their reporting of symptom severity.

having had their illness ‘validated’ by the doctor or the converse in those not in receipt of a prescription. Any study using self-reported diary data may be open to such misclassification bias but if the reported symptoms are accepted at face value then the symptoms recorded in the diary will reflect the patient’s experience of illness. In this observational dataset it is not known how delayed prescribing was operationalised, but, regardless of this, a delayed prescription conferred similar symptomatic benefits to an immediate prescription, with lower prescription uptake.

Comparison with existing literature

In routine care in England, 48% of those presenting with an acute sore throat illness receive an immediate antibiotic prescription and 14% a delayed prescription. Antibiotics for acute sore throat are generally well targeted to those with the most severe symptoms and those most likely to benefit. In this current study, in the sample returning symptom diaries, 60% of those issued a delayed prescription reported using the prescription, which is greater than that reported in experimental studies. Overall use of antibiotics is similar in the US (60%), whereas in France and the Netherlands reported prescribing rates are lower (20% and 23%, respectively), although these are aggregated data for all respiratory consultations.

As would be anticipated, there is some symptomatic benefit in those receiving an antibiotic comparable with that seen in systematic reviews and this effect is also seen in those in receipt of a delayed prescription.

Although this study was not powered to find an interaction of the effect of antibiotic prescribing strategy with the likelihood of streptococcal infection, the point estimates for poorer symptomatic outcome with a no prescription strategy are more pronounced, which suggests that increased likelihood of streptococcal infection may make symptomatic benefit a little more likely when antibiotics are prescribed. Once again, there was no clear benefit from immediate antibiotics compared with delayed antibiotics in individuals more likely to have streptococcal infection.

Implications for research and practice

Systematic reviews have consistently demonstrated that antibiotics confer a modest benefit for symptom relief, and this study has confirmed this effect using evidence from routine practice. The authors have previously demonstrated that antibiotic prescriptions in routine general practice do appear to be targeted at those at greatest risk of streptococcal carriage according to baseline characteristics. Judicious use of antibiotics is an international priority, and there is potential to reduce the uptake of antibiotics through greater use of the delayed prescription technique or through non-prescription. Although adoption of the ‘non-prescribing strategy’ results in the lowest uptake of antibiotics, use of a delayed prescription may be a useful option where current prescribing rates are high or there is greater concern for complications. It is recognised that there is a trade-off between lower antibiotic prescribing and patient satisfaction with both doctors and practices, although clinical trials have not demonstrated large differences in satisfaction between immediate and delayed prescribing. There is also likely a trade-off between a global reduction

in prescribing and an increased risk of septic complications, although the absolute increase is very small.20

Delayed prescribing in this study was targeted at those with intermediate symptom severity; however, trials of delayed prescribing in sore throat were not stratified by symptom severity and symptomatic outcomes were similar for all groups,5 hence it is unlikely that more widespread use of the delayed strategy would result in worse symptomatic outcomes. Caution must be exercised in those with greater probability of streptococcal infection and, although adverse outcomes in those with higher symptom scores using a delayed prescription were not demonstrated in this study, this may be due to lack of power. In one study, using a delayed strategy in combination with a symptom score to target antibiotics did result in both reduced antibiotic consumption and improved outcomes compared with empirical delayed prescribing, and this may be the optimal strategy.10 In routine practice as in trials, delayed prescribing offers comparable symptom control to immediate prescribing [this study], and the authors have previously shown it reduces re-consultation,6 and the risk of septic complications.8

In the full cohort, 14% of sore throat consultations concluded with the issue of a delayed antibiotic prescription. However, there is potential for higher rates to be achieved, for instance, only half of participating practices in this study reported using the delayed strategy. GPs have been shown to overestimate the patient demand for antibiotics,21 and the use of a delayed strategy would be one way of countering this overestimation. If most of those with intermediate symptom severity were offered a delayed prescription, the total uptake of antibiotics would be reduced with no anticipated adverse effects for symptom control, complications, or re-consultation.

Funding
The work was sponsored by the University of Southampton, funded by the Medical Research Council, and supported through service support costs by the National Institute for Health Research. Reference number G0500977. Neither sponsor nor funder had any role in specifying the analysis or in the write-up.
